The transition method for image binarization is based on the concept of \( t \)-transition pixels, a generalization of edge pixels, and \( t \)-transition sets. We introduce a novel unsupervised thresholding for unimodal histograms to estimate the transition sets. We also present dilation and incidence transition operators to refine the transition set. Afterward, we propose the simple edge transition operator for detecting edges. Our experiments show that the new approach increases the effectiveness of OCR applications outperforming several top-ranked binarization algorithms.

1. Introduction

In binarization algorithms, the foreground \( \mathcal{F} \) denotes the subset of pixel of interest, while the background \( \mathcal{B} \) is the complement of \( \mathcal{F} \).

Few binarization researchers work with color images directly [1]. The rest transforms an image from color to gray intensities before applying the binarization algorithm. For example: (1) Chou et al. [2] developed a binarization system for images produced by cameras, which deals with uneven illuminated images. They divide a gray-intensity image into several regions and decide how to binarize each region. (2) Caron et al. [3] detect region of interest characterizing each pixel with a gray-intensity template of \( 3 \times 3 \), the frequency of which appears to obey a power law distribution. (3) Milewski et al. [4] presented a methodology for separating handwritten foreground pixels, from background in carbon copied medical forms. They compare the gray-intensity mean of small neighborhoods around the pixel of interest. (4) and (5) Both Chen et al. [5] and Mello et al. [6] binarize documents using gray-intensity images as input. Whereas Chen et al. generate the binary image from the edge image of the gray-intensity image, Mello et al. compute a threshold based on a weighted entropy equation.

We follow the approach of the previous examples. That is, our method takes a gray-intensity image \( I \) as input and returns a binary image \( B \) as output, where pixels in white represent the background and pixels in black represent the foreground.

We can identify three categories of binarization algorithms [7]. Global algorithms label a given pixel using information from the whole image, while local algorithms rely on information from the pixel neighborhood. Hybrid algorithms combine information from the whole image and from the pixel neighborhood. Note that global algorithms can be transformed into local versions by restricting the analysis to the pixel neighborhood. All algorithms considered in this article are local even though some of them were originally formulated for global analysis. Local versions usually perform better than global ones [7].

Thresholding algorithms classify a pixel as foreground if the gray intensity of the pixel is darker than a threshold. In this line, Sezgin and Sankur [8] present an exhaustive categorization of thresholding. They affirm that Kittler’s minimum error thresholding [9] and Sauvola’s thresholding [10] are the best-scored algorithms binarizing documents uniformly illuminated and degraded with noise and blur. In essence, Kittler’s criterion maximizes the likelihood of the joint distribution of gray intensities assuming that foreground and background are normally distributed with different variances. Otsu’s algorithm [11] minimizes the gray-intensity variances of both foreground and background. In contrast, Portes et al. [12] maximizes the non-extensive entropy, also called Tsallis entropy [13], of both foreground and background.

Sauvola’s algorithm is a modified version of Niblack’s algorithm [14]. Both algorithms assume that the gray intensities of the background are approximately normally distributed and select a
threshold as the lower limit of an interval centered in the mean of the gray-intensity histogram. Wolf and Jolion [15] modified Sauvola’s equation by adding two terms: the minimum gray intensity of the neighborhood and the maximum standard deviation of all neighborhoods. Both act like a dynamic variance-normalization factors.

The key ideas in the methods mentioned above are the following:Niblack, Sauvola and Wolf use statistics from a neighborhood of the pixel of interest, while Kittler, Portes and Otsu define a criterion to optimize and assume an a priori statistical distribution for both foreground and background. However, all six algorithms disregard edge information and this leads to false positive spots and diminished foreground boundaries.

We attempt to extend the transition method proposed in [16]. The concept of t-transition pixel, t-transition set, transition value, and transition function are briefly explained. Later on, we discuss the histogram behavior of transition values. Some mathematical arguments and empirical evidence lead us to propose the double linear thresholding to compute a threshold for transition values in order to approximate the transition set, which is refined by both incidence and dilation transition operators.

Although edge detection is not the main scope of this article, we introduce the simple edge transition operator that is capable to compute the edge image.

This paper considers only one input image without sudden illumination changes in small neighborhoods.

The rest of this paper is organized as follows. Section 2 introduces the main concepts and introduces the concept of transition. The transition method is developed in Section 3. Section 4 describes the design of our experiments. The results are shown in Section 5. Conclusions are presented in Section 6.

2. Preliminary concepts

2.1. Notation

An image function \( F \) can be defined as the mapping \( F : P \rightarrow A \) where \( P = \{p_{ij} | p_{ij} \in \mathbb{N} \times \mathbb{N} \} \) and \( A \subset Z \). The pixel \( p_{ij} \) is located in the \( i \)-th row and the \( j \)-th column. If the pixel position is irrelevant, we denote the pixel \( p_{ij} \) as \( p \). \( I : P \rightarrow G = \{0, 1, \ldots, l\} \) is the gray image function. \( B : P \rightarrow \{0,1\} \) represents the binarization of \( I \), where one is considered as foreground. Local binarization algorithms compute a threshold surface \( T : P \rightarrow G \) over the whole image; \( B(p) = 1 \) if \( I(p) \) is lower than the threshold \( T(p) \). The information to compute \( T(p) \) is gathered from the pixels within a square \( N(p) \) centered at the pixel \( p \) of sides with length \( 2r+1 \).

\[ P(p \in A) \text{ denotes the probability that a pixel } p \text{ belongs to } A \subset P. \]

The mean and variance of any function \( F \) in a set \( A \) are denoted as \( \mu_{F,A} \) and \( \sigma^2_{F,A} \).

The maximum \( F(x) \) value in a set \( A \) is denoted as \( \max_{x \in A} F(x) \) while \( \min_{x \in A} F(x) \) denotes the minimum. Similarly, \( \max_{x \in A} F(x) \) denotes the value of \( x \) that leads to the maximum value of \( F(x) \) in \( A \) while \( \arg \min_{x \in A} F(x) \) the value of \( x \) that leads to the minimum.

We denote \( H_{f,A} \) the histogram of those pixels within \( A \). For instance, \( H_{f,\{N(p)\}} \) denotes the histogram of gray intensities foreground pixels within \( N(p) \).

2.2. Transition set

A pixel \( p \) is a t-transition pixel if the neighborhood \( N(p) \) contains foreground and background pixels. The set of these pixels is named \( P_t \). If \( t = 1 \), then the t-transition pixel is an edge pixel.

A neighborhood that contains a large subset of \( P_t \) also contains a significant subset of the foreground contour. Furthermore, the statistical distribution of the positive transition set \( F_t = P_t \cap F \) approximates the distribution of \( F \) since it is a large foreground sample. Analogously, the distribution of the negative transition set \( B_t = P_t \cap B \) approximates the distribution of \( B \), see Fig. 1.

A transition function \( F \) is a discriminant function that fulfills the following conditions:

1. Extreme positive values for pixels in \( F_t \).
2. Extreme negative values for pixels in \( B_t \).
3. \( F \) takes values close to zero in \( P_t \).

Formally, these conditions can be expressed in terms of conditional probabilities:

\[
\begin{align*}
\Pr(p \in F_t | F(p) \geq t_+) & > 1 - \varepsilon_+, \\
\Pr(p \in B_t | F(p) \leq t_-) & > 1 - \varepsilon_-, \\
\Pr(p \in (P_t \setminus F) | t_+ < F(p) < t_-) & < 1 - \varepsilon,
\end{align*}
\]

where \( \varepsilon_+ < 0.5 \), \( \varepsilon_- < 0.5 \), and \( \varepsilon < 0.5 \), but the closer they are to zero, the better. Eqs. (1) and (2) mean \( p \) is pre-classified as foreground when \( F(p) \) is greater than \( t_+ \). In contrast, \( p \) is pre-classified as background when \( F(p) \) is lower than \( t_- \). Note that there is no information to pre-classify \( p \) if \( t_- < F(p) < t_+ \).

The previous equations suggest the max–min function \( V \) to measure a transition value:

\[
V(p) = \left( \max_{q \in N(p)} I(q) - I(p) \right) - \left( \min_{q \in N(p)} I(q) - I(p) \right) \equiv \max_{q \in N(p)} I(q) + \min_{q \in N(p)} I(q) - 2I(p). \tag{4}
\]

The analysis of the sampling bias is beyond the scope of this paper. Readers interested in pursuing the topic further are encouraged to consult the books by [17,18] for a more thorough explanation. Useful discussion is also available in [19,20].
Fig. 1 exemplifies two transition pixels \( b \) and \( c \). Without considering outliers, we expect that \( V(c) \approx \max_{p \in N_t} [l(p) - l(c)] \) and \( \min_{p \in N_t} [l(p) - l(c)] \approx 0 \) because the pixel with minimum gray intensity in \( N_t \) is foreground and has to be similar to the gray intensity of \( c \) (foreground smoothness). Moreover, \( \max_{p \in N_t} [l(p) - l(c)] \) has to be higher than the minimum contrast expected in the image because it is the gray-intensity difference between foreground and background pixels. On the contrary, \( V(d) \approx 0 \) because both maximum and minimum gray intensity within \( N_t(d) \) have to be similar to \( d \).

The concept of transition pixel, transition set and transition function were proposed and widely explained by Ramírez-Ortega et al. [16].

We denote \( H_{i,A}(\cdot) \) the transition-value histogram of the pixels within \( A \). For instance, \( H_{i,F} \) denotes the histogram of transition values of foreground pixels.

3. Description of the transition method

Since \( F_t \) and \( B_t \) are dual sets, we will explain only the method for \( F_t \) leaving out details for \( B_t \).

3.1. Overview of the transition method

Consider that Fig. 2(a) is a neighborhood \( N_t(p) \); the left peak of the gray-intensity histogram \( H_{i,N_t(p)} \) is mainly formed by foreground pixels, while the right peak is formed by background pixels. If we knew the class-conditional density \( P(l(q)|q \in F \cap N_t(p)) \), we could consider the maximum likelihood estimation or Bayesian estimation approach to solve the binarization problem. Unfortunately, we rarely know the class-conditional densities. However, we can reasonably assume that the gray intensities of the foreground are approximately normally distributed with mean \( \mu_i \) and variance \( \sigma_i^2 \) in small neighborhood \( F \cap N_t(p) \).

That is

\[
H_{i,F\cap N_t(p)}(l) \approx c_i \phi(l; \mu_i, \sigma_i^2),
\]

where \( c_i \approx |F_t \cap N_t(p)| \) and \( \phi(l; \mu, \sigma) \) denotes the normal probability density function with mean \( \mu \) and variance \( \sigma^2 \). \( T(p) \) is quickly computed when there is an analytic intersection between \( c_i \phi(l; \mu_i, \sigma_i^2) \) and the correspondent background function \( c_j \phi(l; \mu_j, \sigma_j^2) \), see Fig. 2(b).

We can approximate \( P(l(q)|q \in F \cap N_t(p)) \) by drawing a representative sample of \( F \cap N_t(p) \). The positive transition set \( F_t(p) \) satisfies

\[
P(l(q)|q \in F \cap N_t(p)) \approx P(l(q)|q \in \hat{F}_t \cap N_t(p)).
\]

Hence, \( F_t \cap N_t(p) \) is a representative sample of \( F \cap N_t(p) \), see Fig. 2(c).

Although the transition sets are also unknown, our method provides \( \hat{F}_t \) which is an accurate estimate of \( F_t \), see Fig. 2(d).

Thus, (6) changes to

\[
P(l(q)|q \in F \cap N_t(p)) \approx P(l(q)|q \in \hat{F}_t \cap N_t(p)).
\]

We are now able to compute the gray threshold with usual classification procedures. In Table 1, for instance, we computed the minimum symmetric value as

\[
s_A = \min_{l \in \mathbb{R}} \frac{1}{n_{l,a}(0)} \sum_{j=1}^{k} [H_{i,A}(i+j)-H_{i,A}(i-j)],
\]

where \( A \) is a set of pixels and \( k \leq 1/2 \) is an integer.

Fig. 2. (a) Gray-intensity image of the neighborhood \( N_t(p) \) and gray-intensity histogram \( H_{i,N_t(p)} \) of pixels within \( N_t(p) \). (b) Binary ground truth and histogram of gray intensities of both foreground and background. We have manually fitted a normal probability density distribution function to each histogram. (c) Transition sets. In blue, pixels within the positive transition set \( F_t \), while pixels within the negative transition set \( B_t \) are shown in red. In \( N_t(p) \), the density of gray intensities of \( B_t \) and \( F_t \) approximate the gray-intensity densities of \( B \) and \( F \), respectively. (d) Approximation of the transition sets. We use the approximation of positive and negative transition sets as foreground and background samples, respectively. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)
We define $\mathcal{P}_t(p) = \mathcal{P}_t \cap \mathcal{N}_t(p)$ and $\mathcal{P}_t’(p) = \mathcal{P}_t \cap \mathcal{N}_t’(p)$. We define $\mathcal{F}_t(p), \mathcal{F}_t’(p), \mathcal{B}_t(p)$, and $\mathcal{B}_t’(p)$ in a similar manner.

The complete method consists of the following steps:

1. Compute the transition values for each pixel with a transition function. We suggest the max–min function using neighborhoods of radius 2, see Fig. 3(b).
2. Calculate the thresholds $t_+$ and $t_-$. Take $\mathcal{F}_t = (p \mid V(p) \geq t_+)$ and $\mathcal{B}_t = (p \mid V(p) \leq -t_-)$ (Section 3.2), see Fig. 3(b).
3. Restore $\mathcal{F}_t$ and $\mathcal{B}_t$ (Section 3.3), see Fig. 3(f, g).
4. Label $p$ using information from $\mathcal{F}_t(p)$ and $\mathcal{B}_t(p)$ (Section 3.4).
5. If binarization: Compute $\mathcal{I}(p)$ (Section 3.4.1), Fig. 3(h).
6. If edge detection: Compute simple edge transition operator (Section 3.5).
7. Remove noise from $B$ with standard algorithms.

3.2. Transition threshold

We find a suitable transition threshold by analyzing functions of the transition values:

**Empirical scaled density function:**

$$u_i = \frac{1}{k} H_{V,\gamma}(i) \quad \text{where} \quad k = \max_{i \in [1,k]} H_{V,\gamma}(i).$$

**Empirical complementary cumulative distribution function:**

$$v_i = \frac{1}{k} \sum_{j=1}^{i} H_{V,\gamma}(j) \quad \text{where} \quad k = \sum_{j=1}^{n} H_{V,\gamma}(j).$$

The behavior of the positive transition values (Fig. 4(a)) will appear to have a heavy right tail. The power-law distribution has been discarded because the log–log plot (Fig. 4(b)) of the empirical complementary cumulative distribution (CCD) function does not follow the characteristic straight-line form of the power-law distribution [21].

Fig. 4(a) shows two linear zones. The first linear relation mostly corresponds to non-transition set $\mathcal{P}_t'$ having positive transition value. The second linear part is mainly formed by transition pixels. Indeed, the histogram of positive transition values is a combination of three histogram as is shown in Fig. 4(b). Thus, a criterion to select the transition threshold $t_+$ is to take the value $t$ that divide the graph, using linear–linear or linear–log scales, into approximately two lines.

3.2.1. Double-linear threshold for transition values

The double-linear method approximates the positive side of the transition graphs ($i w_i$) by joining two linear functions, see Fig. 5(a), where $w_i$ is computed as (8) or (9). However, the transition graph is truncated between the bounds $x_{\min}$ and $x_{\max}$ in order to reduce the noise in the first and last values of the graph, where $x_{\min}$ is the minimum index $i$ that satisfies

$$w_i > w_{i+1} \quad \text{and} \quad w_i > w_{i+2} \quad \text{and} \quad w_{i+1} > w_{i+2} \quad \text{(10)}$$

and $x_{\max}$ is the maximum index $i$ that satisfies

$$\frac{w_i}{w_{x_{\max}}} > \delta, \quad \text{(11)}$$

such that $\delta > 0$ is small (we suggest $\delta = 0.01$). For mathematical convenience, we re-label our values $w_i$ as

$$y_i = w_i - x_{\min} \quad \text{for} \quad i = 0, 1, \ldots, x_{\max} - x_{\min} = n \quad \text{(12)}$$

and postulate that $y_i$ satisfies (13) and (14):

$$y_i \approx m_1 \cdot i + b_1 \quad \text{if} \quad i = 0, 1, 2, \ldots, t, \quad \text{(13)}$$

$$y_i \approx m_2 \cdot i + b_2 \quad \text{if} \quad i = t, t+1, \ldots, n. \quad \text{(14)}$$

---

2 We have constructed a formal treatment of this argument using some probability assumptions over the gray-intensity differences. This work has been submitted for publication.
Fig. 4. (a) Estimated histogram of the positive transition set $\mathcal{F}_t$ given the histogram of positive transition values. (b) The log–log plot of the empirical complementary cumulative distribution functions of the positive transition pixels does not follow the characteristic straight-line form of the power-law distribution.

Fig. 5. (a) The scaled density function is approximated by the joining of two lines $L_1$ and $L_2$. (b) Plot of $\text{Error}_1(t) + \text{Error}_2(t)$ between $x_{\text{min}}=3$ and $x_{\text{max}}=30$.

We use the differences rate estimator [22] to compute $\hat{m}_1$. This estimator is defined as

$$\hat{m}_1 = \frac{6}{n(t+1)(t+2)} \sum_{t=0}^{t} (2i-t)y_i.$$  (15)

However, the slope can be computed by regression methods as in [23,24].

Unfortunately, there is no differences-rate estimator for the intercept term $b$, therefore we use the least-square estimator

$$\hat{b}_1 = \frac{1}{t+1} \sum_{i=0}^{t} (y_i - \hat{m}_1 \cdot i).$$  (16)

A natural error function for (13) can be defined as

$$\text{Error}_1(t) = \sum_{i=0}^{t} (y_i - \hat{m}_1 \cdot i - \hat{b}_1)^2.$$  (17)

In the same way, an error function for (14) is defined as

$$\text{Error}_2(t) = \sum_{i=1}^{n} (y_i - \hat{m}_2 - x_i \cdot i - \hat{b}_2)^2,$$  (18)

where

$$\hat{m}_2 = \frac{6}{n(t)(n-t+1)(n-t+2)} \sum_{i=0}^{n-t} (2i+n+t)y_i$$  (19)

and

$$\hat{b}_2 = \frac{1}{n-t+1} \sum_{i=t}^{n} (y_i - \hat{m}_2 i).$$  (20)

Finally, $t_+$ is computed as

$$t_+ = \arg \min_{t \in \{1,n\}} \text{Error}_1(t) + \text{Error}_2(t) + x_{\text{min}} + 2.$$  (21)

3.3. Restoration of transition set

The restoration of the transition set $\hat{\mathcal{F}}_t$ is the process of adding and removing pixels from $\mathcal{F}_t$ with the aim of increasing the cardinality while reducing the noise.

Morphological operators, like erosion and dilation [25], could be adapted to enhance $\hat{\mathcal{F}}_t$. However, those operators will add or remove pixels without considering neither gray intensities nor transition values. Those operators in their original form will alter the trusty foreground sample $\hat{\mathcal{F}}_t$, loosing the confidence in the transition set approximation. We propose morphological operators that preserve the confidence of the transition set approximation.

3.3.1. Isolation transition operator

The cross and diagonal isolate operators were successfully used in [16] in order to remove false positives of the approximated transition sets. The cross isolate operator is defined as

$$\text{Given } p \in \hat{\mathcal{F}}_t, \text{ set } \hat{\mathcal{F}}_t ^- \leftarrow \hat{\mathcal{F}}_t \setminus \{p\} \text{ if } |\hat{\mathcal{F}}_t \cap N_{\oplus}(p)| = 0.$$  (22)

where $N_{\oplus}(p_j) = \{p_{j-1,1},p_{j+1,1},p_{j-1,j},p_{j+1,j}\}$. Instead the cross neighborhood, the diagonal transition operator uses the diagonal neighborhood $N_{\odot}(p_j) = \{p_{j-1,j-1},p_{j-1,j},p_{j-1,j+1},p_{j+1,j},p_{j+1,j-1},p_{j+1,j+1}\}$.

Some applications, like text recognition or fingerprint classifier, assume that the foreground consists of large connected components. These components are commonly larger than a particular rectangular area. Then, the connected components that are completely contained in small rectangular neighborhoods may be removed. We define the rectangular transition operator as

$$\text{Given } p \in \hat{\mathcal{F}}_t, \text{ set } \hat{\mathcal{F}}_t ^- \leftarrow \hat{\mathcal{F}}_t \setminus \{p\} \text{ if } p \in \hat{\mathcal{F}}_t \text{ and } |\hat{\mathcal{F}}_t \cap N_{\odot}(p)| = 0.$$  (22)

where $N_{\odot}(p_j) = \{p_{j-1,j-1},p_{j-1,j},p_{j-1,j+1},p_{j+1,j},p_{j+1,j-1},p_{j+1,j+1}\}$.

3.3.2. Removal transition operator

$$\text{Given } p \in \hat{\mathcal{F}}_t, \text{ set } \hat{\mathcal{F}}_t ^+ \leftarrow \hat{\mathcal{F}}_t \setminus \{p\} \text{ if } |\hat{\mathcal{F}}_t \cap N_{\ominus}(p)| = 0.$$  (23)

where $N_{\ominus}(p_j) = \{p_{j-1,j},p_{j+1,j},p_{j-1,j+1},p_{j+1,j-1}\}$ and $N_{\ominus}(p_j) = \{p_{j-1,j},p_{j+1,j},p_{j-1,j+1},p_{j+1,j-1}\}$.
3.3.2. Incidence transition operator

The blue pixels in Fig. 6(a) depict pixels with high positive transition value. In red, those pixels with high negative transition value. In the same figure, whereas the isolated blue pixel \( \textbf{q} \) (right-bottom corner) is an outlier and easily removed by cross, diagonal or rectangular transition operators, the red pixels around \( \textbf{q} \) form a large “isolated” connected component (24 pixels) that cannot be removed by those operators.

By definition, a background \( t \)-transition pixel \( \textbf{p} \) contains at least one foreground \( t \)-transition pixel in \( \mathcal{N}_t(\textbf{p}) \). That is \( |\mathcal{F}_t(\textbf{p})| \geq 1 \), if \( \textbf{p} \in \mathcal{P}_t \). Moreover, \( |\mathcal{F}_t(\textbf{p})| > |\mathcal{F}_t(\textbf{p})| \) in most of the transition pixels. Thus, the neighborhood \( \mathcal{N}_t(\textbf{p}) \) of a pixel with high positive transition value may contain several pixels with high positive transition value. An example is Fig. 6(a), where \( |\mathcal{F}_2(\textbf{p})| = 1 \) and \( |\mathcal{F}_2(\textbf{p})| = 8 \). In opposite to \( \textbf{p} \), the pixel \( \textbf{q} \) and all the red pixels around it only contains one blue pixel in \( \mathcal{N}_2(\textbf{q}) \).

To deal with pixels like \( \textbf{q} \), we define a generalization of isolated transition pixel as: Given two positive integers \( a \) and \( b \), a pixel \( \textbf{p} \in \mathcal{P}_t \) is a \( k \)-isolated transition pixel if

\[
|\mathcal{F}_t(\textbf{p})| < a \quad \text{or} \quad |\mathcal{F}_t(\textbf{p})| < b.
\]

(24)

The incidence transition operator removes all the \( k \)-isolated transition pixels. We recommend setting \( k = 2t \), \( a = b = 1 + t \).

3.3.3. Dilation transition operator

Suppose that \( \textbf{p} \) and \( \textbf{q} \in \mathcal{N}_t(\textbf{p}) \) are two foreground pixels such that \( \textbf{q} \in \mathcal{F}_t \) and \( \textbf{p} \notin \mathcal{F}_t \), thus \( V(\textbf{q}) \geq t \) and \( V(\textbf{p}) < t \). This implies that \( \textbf{p} \) is excluded from \( \mathcal{F}_t \). However, we can assume

\[
P(l(\textbf{q}) \geq l(\textbf{p})) \approx P(l(\textbf{q}) \leq l(\textbf{p})) \quad \text{if} \quad \textbf{p}, \textbf{q} \in \mathcal{F} \cap \mathcal{N}_t(\textbf{p})
\]

(25)

because \( l(\textbf{q}) \approx l(\textbf{p}) \) for all \( \textbf{q} \in \mathcal{F} \cap \mathcal{N}_t(\textbf{p}) \). So,

\[
P(l(\textbf{q}) \geq l(\textbf{p})) \approx P(l(\textbf{q}) \leq l(\textbf{p})) \quad \text{if} \quad \textbf{p}, \textbf{q} \in \mathcal{F}_t(\textbf{p}).
\]

(26)

In other words, about half of the pixels in \( \mathcal{F}_t(\textbf{p}) \) have a gray intensity equal or lower than \( l(\textbf{p}) \) (Fig. 6(b), top). In addition, the gray intensities of the background are strictly higher than \( l(\textbf{p}) \) in the ideal case. Therefore, the number of pixels that are equal or lower in gray intensity than \( l(\textbf{p}) \) may be zero or close to zero.

Table 2 is constructed following the same reasoning, although a formal proof of the probabilities is beyond the scope of this paper.

Using the conditional probabilities of Table 2, a high number of pixels in \( \mathcal{F}_t(\textbf{p}) \) that are equal or lower in gray intensity than \( l(\textbf{p}) \) is a strong evidence that \( \textbf{p} \) belongs to the foreground. We derived a similar argument for background pixels.

To measure this conditional probabilities, we define the \( t \)-transition balance:

\[
TB_t(\textbf{p}) = |\{\textbf{q} \in \mathcal{F}_t(\textbf{p}) | l(\textbf{q}) \geq l(\textbf{p})\}| - |\{\textbf{q} \in \mathcal{B}_t(\textbf{p}) | l(\textbf{q}) \geq l(\textbf{p})\}|.
\]

(27)

So, \( TB_t(\textbf{p}) \approx \frac{1}{2} |\mathcal{F}_t(\textbf{p})| \) if \( \textbf{p} \) is foreground, and \( TB_t(\textbf{p}) \approx -\frac{1}{2} |\mathcal{B}_t(\textbf{p})| \) if \( \textbf{p} \) is background. Hence, \( TB_t(\textbf{p}) \) is approximated with \( \hat{T}_t(\textbf{p}) \) which uses \( \hat{P}_t(\textbf{p}) \) instead of \( p_t(\textbf{p}) \).

Given \( \textbf{p} \notin \mathcal{P}_t \), the dilation transition operator set

\[
\hat{F}_t \leftarrow \hat{F}_t \cup \{\textbf{p}\} \quad \text{if} \quad \hat{T}(\textbf{p}) \geq a
\]

(28)

and

\[
\hat{B}_t \leftarrow \hat{B}_t \cup \{\textbf{p}\} \quad \text{if} \quad \hat{T}(\textbf{p}) \leq -b.
\]

(29)

where \( a \) and \( b \) are two positive integers. We recommend setting \( a = b = 1 + t \).

3.4. Positive and negative sets

Only pixels in \( \hat{F}_t(\textbf{p}) = \hat{F}_t(\textbf{p}) \cup \hat{B}_t(\textbf{p}) \) are considered to compute \( T(\textbf{p}) \). At the same time, outliers are discarded by labeling as background those pixels \( \textbf{p} \) that satisfy either \( |\mathcal{F}_t(\textbf{p})| < m_+ \) or \( |\mathcal{B}_t(\textbf{p})| < n_+ \), where \( n_+ \) and \( m_+ \) depend on \( t \) and objects of interest; the higher the \( n_+ \), the larger the objects that can be removed from the foreground. For instance, consider a simple horizontal line with height 1 as the foreground. The line’s extremes are evaluated if \( n_+ = t + 1 \). Otherwise, the line’s extremes are labeled as background without even computing \( T(\textbf{p}) \). We suggest \( n_+ = n_+ = 5 \) for detecting small foreground objects.

A second criterion to discard outliers uses the difference between the mean of gray intensities of both transition set approximations. The pixel \( \textbf{p} \) is labeled as background if

\[
H_{t, \mathcal{F}_t}(\textbf{p}) - H_{t, \mathcal{B}_t}(\textbf{p}) < c
\]

(30)

where \( c \) is an integer, which depicts the minimum contrast expected between the foreground and background. We suggest \( c = 15 \).

Table 2

The probability of the inequality is approximated given \( \textbf{p} \) and \( \textbf{q} \in \mathcal{N}_t(\textbf{p}) \).

Fig. 6. (a) The transition values were computed using \( \mathcal{N}_2 \). The pixels with high positive value are shown in blue, in red the pixels with high negative value. (b) Bottom: the gray-intensity of the blue pixel in \( \mathcal{N}_2(\textbf{p}) \) is lower or equal to \( l(\textbf{p}) \), (b) Top: the approximation of the transition balance of \( \textbf{p} \). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)
2.4.1. Statistical thresholds

Normal threshold: Assume that \( H_{I_1,i,j,p}(i) \approx c_+ \phi(i; \mu_+, \sigma^2_+) \), where \( \phi(x; \mu, \sigma) \) is the normal probability density function with mean \( \mu \) and variance \( \sigma^2 \). Then, \( H_{I_1,i,j,p} \) is approximated when

\[
\begin{align*}
c_+ &= |\mathcal{F}_{1,i,j}(p)| \quad \text{(complete form)} & c_+ &= 1 \quad \text{(simple form)}, \quad \\
\mu_+ &= \mu_{i,j,p}, \quad \\
\sigma^2_+ &= \max(\sigma_{i,j,p}^2, 1).
\end{align*}
\]

(31)

The intersection of those curves is the root \( \mu_+ < x_0 < \mu_- \) of the quadratic equation with coefficients \( a, b \) and \( c \) given by

\[
\begin{align*}
a &= \frac{1}{\sigma^2_+} - \frac{1}{\sigma^2_-}, \\
b &= \frac{2\mu_+}{\sigma^2_+} - \frac{2\mu_-}{\sigma^2_-}, \\
c &= \frac{\mu^2_+ - \mu^2_-}{\sigma^2_+ - \sigma^2_-} - 2\ln\left( \frac{\sigma_+}{\sigma_-} \cdot \frac{\sigma_-}{\sigma_+} \right).
\end{align*}
\]

(32)

Lognormal threshold: Assume that \( H_{I_1,i,j,p}(i) \approx c_+ \lambda(i; \mu_+, \sigma^2_+) \), where \( \lambda(x; \mu, \sigma^2) \) denotes the lognormal probability density function with parameters \( \mu \) and \( \sigma^2 \).

The intersection is computed using the root \( x_0 \) of the quadratic equation with coefficients given by (32). This corresponds to \( \exp(x_0) \).

In practice, the parameters \( \mu_+ \) and \( \sigma^2_+ \) are estimated based on the estimated mean and variance of the lognormal distribution using the relations

\[
\begin{align*}
\mu_+ &= \ln(\mu_{i,j,p}) - \frac{1}{2} \sigma^2_- \quad \text{and} \quad \\
\sigma^2_+ &= \ln\left( 1 + \frac{\sigma^2_{i,j,p}}{|\mu_{i,j,p}|} \right).
\end{align*}
\]

(33)

3.5. Edge detection

In binarization context, an edge pixel \( p \) can be defined as a foreground pixel that contains background pixels within \( \mathcal{N}_1(p) \). Therefore, \( \mathcal{F}_1 \) is the set of edge pixels. We could define an edge pixel \( p \) as the pixel that contains both foreground and background pixels within \( \mathcal{N}_1(p) \), or as those background pixels that contain foreground pixels in the neighborhood of radius 1. Nevertheless, we prefer the first edge pixel definition.

We can approximate \( \mathcal{F}_1 \) by

\[
\hat{\mathcal{F}}_1 = \{ p \in \mathcal{F}_1 \quad \text{and} \quad |\mathcal{B}_{1,j}(p)| > 0 \}.
\]

(34)

The pixel \( p \) in Fig. 7(b), which belongs to \( \hat{\mathcal{F}}_1 \), can be considered as an edge pixel since it is exactly between pixels in \( \hat{\mathcal{F}}_1 \) and \( \hat{\mathcal{B}}_1 \). Hence, we define the simple edge transition operator as

\[
\hat{\mathcal{F}}_1 = \{ p \quad \text{if} \quad |\hat{\mathcal{F}}_1(p)| > 0 \quad \text{and} \quad |\hat{\mathcal{B}}_1(p)| > 0 \}.
\]

(35)

Fig. 8(b)–(d) were computed on MatLab [26] using Canny [27], Prewitt [28] and Roberts Cross methods, respectively. Fig. 8(f) was computed following steps 1 and 2 of the transition method (Fig. 8(e)) and applying the simple edge transition operator. The raw transition set approximation (without restoration process) generates many false positives. In contrast, Fig. 8(h), which follows the transition method with a restored transition set, reports a lower number of false negatives than Fig. 8(f). Unfortunately, the combination of transition operators used in Fig. 8(e) includes more than one cross, diagonal and incidence transition operators in a non-trivial order.

The default parameters of MatLab are chosen heuristically in a way that depend on the input data.
4. Design of experiments

To perform an objective evaluation of the binarization results, we have used an unsupervised measure, based on gray-intensity variances, and an optical character recognition (OCR) software.

4.1. Test images

Historical documents usually present several kinds of degradations, such as ink stains, burned areas, weak ink strokes and wide variations in the background. Thus, the binarization algorithms were tested with digitalized images of the historical atlas “Theatrum orbis terrarum, sive, Atlas novus” (Blaeu Atlas) [29] at 150 dpi resolution.

We reported the results of $n=86$ images $I_i$ for $i=1,…,n$, extracted from 61 maps. These images are mainly composed of handwritten characters, see Fig. 9.

4.2. Description of binarization algorithms

We compare Kittler’s [9], Otsu’s [11], Portes’s [12], Sauvola’s [10], Wolf’s [15] methods (top ranked by [7,8,30]) with four variants of the transition method. We implemented all nine algorithms in their local versions to increase their accuracy, despite local implementations raise the running-time dramatically.

Because Kittler’s, Otsu’s and Portes’s algorithms assume that the set of pixels can be divided into two clusters, computing $T(p)$ with these algorithms will systematically produce false positives due to neighborhoods that are completely contained in the background. To avoid these false positives, $T(p) = t^*$ if the difference between the gray-intensity means of the clusters is higher than $c$, where $t^*$ is the optimal local threshold according to the binarization algorithm and $c$ depicts the minimum contrast expected between the foreground and the background. Otherwise the pixel is classified as background. The difference of gray-intensity means between the clusters is given by

$$\mu_0 - \mu_1 < c$$

with $\mu_i = \frac{1}{|C_i|} \sum_{q \in C_i} I(q)$ for $i = 0, 1$,

$$C_0 = \{q \in C_f(p) | I(q) \leq t^*\} \text{ and } C_1 = \{q \in C_f(p) | I(q) > t^*\}.$$  

Real applications rarely use more than one parameter set. This is the main reason we fixed Sauvola’s $x = 0.5$ and $\beta = 128$, Portes’s $x = 2$, and Wolf’s $x = 0.5$, which are the recommended parameters.4

We named our four variants as T-DF-N, T-DF-L, T-CCD-N and T-CCD-L depending on how the algorithm computes the transition and gray-intensity thresholds.

We also tested three variants of T-CCD-L in order to analyze the influence of transition operators on the transition method: T-CCD-L-A does not include any transition operator, T-CCD-L-B includes only the isolate transition operators, and T-CCD-L-C includes both isolate transition operators and incidence transition operators.

4.3. Post-processing step

All binarized images were post-processed removing from the foreground small stains (connected components containing four or less pixels) before computing any evaluation measure. The following operators were applied in this order: cross operator,
diagonal operator and rectangular operator \((x=y=2)\) which correspond to cross, diagonal and rectangular transition operators but filtering the binary image.

4.4. Evaluation measures

Since there is not a public standard benchmark available for binarization algorithms, we use the uniform variance (UV) measure [16]

\[
UV = \sum_{p \in U} \frac{\sigma_x(p) \cdot |S \cap N_r(p)| + \sigma_y(p) \cdot |F \cap N_r(p)|}{|N_r(p)|}
\]

to evaluate the image segmentation quality.

Besides the UV measure, we used TopOCR [31] to recognize the text from binarized images. Our evaluation measures are accuracy (AC) and precision (PR) computed as

\[
AC = \frac{\#(\text{characters of } T_{\text{match}})}{\#(\text{characters of } T_{\text{in}})} \quad \text{and} \quad PR = \frac{\#(\text{characters of } T_{\text{match}})}{\#(\text{characters of } T_{\text{out}})}
\]

where \(T_{\text{in}}\) is the original text in the image, \(T_{\text{out}}\) denotes the recognized text from the OCR, and \(T_{\text{match}}\) denotes the maximum matching text between \(T_{\text{in}}\) and \(T_{\text{out}}\). \(T_{\text{match}}\) is computed using Needleman–Wuntsh algorithm [32].

TopOCR was tested with four parameter sets. The program tester reports the AC and PR measures from the parameter set that scores higher in terms of AC measure. If there is any draw, PR measure is used.

AC measure is an important measure for OCR applications, because a high AC measurement increases the possibility to extract, by further algorithms, relevant information. However, the mean and variance of AC performance \(x^{\text{AC}}\), for each binarization method \(j\) and image \(I_i\), highly depend on the maximum AC performance \(x^*\) that the OCR can compute for \(I_i\). Consequently, we cannot infer from \(x_j\) how effective is the algorithm \(j\) to maximize the OCR performance. For instance, suppose that \(x^*_i < 0.3\), for \(i=1,\ldots,n\), this implies that the average of \(x_j\) (fixing \(j\)) is lower than 0.3. However, we cannot affirm that the binarization algorithm \(j\) is ineffective to maximize the OCR performance. Hence, our observations are mainly based on pairwise tables and the ratio \(y_j\) of \(x_j\) to \(x^*\). This ratio represents the AC efficacy of algorithm \(j\) to maximize the AC performance in \(I_i\). We have computed \(x^*_j\) by sweeping parameters (including the neighborhood radius) of Kittler’s, Niblack’s, Otsu’s, Porte’s, Sauvola’s and Wolf’s algorithms.

Each cell \((y, x)\) of the pairwise tables contains two values \(n_{yx}\) and \(p_{yx}\). The number \(n_{yx}\) represents the times that the algorithm \(y\) has a higher score than the algorithm \(x\), while \(p_{yx} = n_{yx}/(n_{yx} + n_{xy})\) represents the conditional probability of \(y\)’s score being higher than \(x\)’s score. We based our observations on the values \(p_{yx}\). We ascertain that algorithm \(x\) is better than algorithm \(y\) if \(n_{yx} \geq 1.33n_{xy}\), which is equivalent to \(p_{yx} \geq 0.57\).

5. Results

We arranged the test images such that the graph of AC performance is decreasing. That is \(x^*_j \geq \cdots \geq x^*_n\). However, Fig. 11(a) shows that AC performance of Otsu’s and T-CCD-L methods fluctuates irregularly although \(x^*_n\)’s graph is decreasing. We cannot visually assess the binarization performance because of the fluctuations.

To deal with these fluctuations, we present graphs and statistics of points \((i/n, y_{x,y})\) where \(z_{ij}\) are indexes such that \(y_{z_{ij}} \geq \cdots \geq y_{z_{in}}\) for each binarization method \(j\). UV measure penalizes eroded and overestimated foreground boundaries, but it also penalizes stains (ink stains and dark background spots) that are classified as background so that algorithms that compute foreground boundaries correctly and classify stains as foreground are highly scored, like Wolf’s thresholding that is the best in terms of UV measure, see Table 3.

![Fig. 11. (a) The graph of the maximum AC performance is decreasingly arranged. (b) Ordered AC efficiency of no-transition algorithms.](image)

</table>

The cell \(y, x\) shows how many times the algorithm \(y\) surpass the algorithm \(x\) in terms of UV measure. T-CCD-L and T-DF-N have even scores in a couple of images. The highest values are shown in bold.
However scattered stains and a slight overestimate of the foreground contour lead Wolf’s method to low OCR performance, see Tables 4–6.

Kittel’s thresholding also classifies stains as foreground but, contrary to Wolf’s method, it overestimates the foreground boundaries greatly. In consequence, Kittler’s method is a medium rank in terms of UV measure and reports the lowest AC efficacy because of the overestimated foreground boundary, see Fig. 11.

Sauvola’s algorithms compute low thresholds, which discard stains from the foreground, but low thresholds also produce eroded foreground boundaries that are strongly penalized by UV measure (Table 3). As a result, Sauvola’s method was the worst in terms of UV. What is more, this also affects the OCR performance badly (Table 3).

Portes’s classifies stains as foreground frequently and overestimates the foreground contour slightly. In combination, this reduces the OCR performance but increases the UV measurements.

Otsu’s and transition algorithms determine sharp foreground contours. However, Otsu’s generated a great deal of stains in neighborhoods that are completely contained in the background despite the restriction of (36).

Transition algorithms differ as a product of two factors: the function that computes the transition thresholds and the function that computes the gray-intensity thresholds. Transition algorithm based on the complementary cumulative distribution resists more noise than those based on the density distribution so that both T-CCD-L and T-CCD-N generate less stains (penalized

UV measurements) than T-DF-L and T-DF-N. Therefore, they have the highest AC efficacy, see means and variances in Fig. 12. On the other hand, transition algorithms based on lognormal threshold have a sharper foreground contour than those based on the normal threshold. Although these differences are visually minimal, they are reflected on the UV measurements.

We only present the influence of transition operator in T-CCD-L and variants A, B and C because the rest of transition methods are influenced in a similar manner.

The relative high variance of T-CCD-L-A and the graph behavior of the AC efficacy, see central-right graph of Fig. 13 and Table 7, suggest that T-CCD-L-A resists moderate noise.

Incidence and isolate transition operators increase the AC efficacy in images with high noise level at the cost of dropping the cardinality of transition set and, in consequence, the AC efficacy decreases in images whose foreground contains small connected component like punctuation marks and small characters. However, the incidence operator does not remove dense salt and pepper noise. Thus, it has to be applied after isolate transition operators.

Dilation transition operator counterbalances the unwanted effect of the incidence and isolate transition operators by increasing the cardinality of diminished transition sets. We should remark that this operator has to be applied in images with low noise level, or after isolate and incidence transition operators. Otherwise, the noise is magnified.

6. Conclusions

Our double-linear method is able to compute an accurate threshold which selects a representative samples of both foreground and background. We introduced three transition operators: both incidence and dilation transition operators refine transition set approximations, while the simple edge transition operator detects foreground edges.

Our test used a large database of text extracted from historical maps with different levels of degradation. We evaluated our experiments with four measures: an unsupervised evaluation method based on gray-intensity variances (UV measure) and three OCR measures (AC, PR measure and AC efficacy).

Our results point out that the transition method resists highest levels of noise. These tables also indicate that the complementary cumulative distribution function decreases the impact of outliers on the double-linear threshold and the use of lognormal threshold generates sharper foreground contours. Moreover, while the incidence transition operators can remove noise that isolate operators cannot, the dilation transition operator improves the performance of normal and lognormal thresholds.
